Addressing SRAM verification challenges

SureCore demonstrates robust low power memory for power critical applications with Solido Variation Designer

Executive summary
SureCore Limited is an SRAM IP company based in Sheffield, the United Kingdom, that develops low power memories for current and next generation silicon process technologies. Its award-winning, world-leading, low power SRAM designs are process independent and variability tolerant, making them suitable for a wide range of technology nodes. Two major product families have been announced: PowerMiser™ and EverOn™. PowerMiser is a general purpose SRAM capable of delivering in excess of 50 percent dynamic and 20 percent static power savings compared to industry standard offerings. EverOn is a memory developed specifically for the IoT and wearable markets. It delivers near threshold operating voltages facilitating extremely low power operation. Both product families are based on standard foundry bit cells and no process modifications are needed to deliver these capabilities. Key to achieving market leading low power performance is a comprehensive verification strategy. In this paper, co-written with our partners at Siemens EDA, the key elements of this strategy will be explored, including focused parametric tests run with Monte Carlo (MC) analysis across the PVT range and high sigma analysis, using Solido™ Variation Designer.

| Introduction |

Verification is an integral part of any integrated circuit development process. The verification process must establish that the design meets its specified yield and performance criteria over the full range of operating conditions before tape-out sign-off. The process generally involves taking abstractions of the design in appropriate forms, for example post-layout extracted netlists, and running simulations to validate the design performance. The verification process must address many different aspects of yield and performance, so several different types of design abstraction and simulation tooling may be required to complete the process. In the case of SRAM this is particularly true.

Verification of a complete compiler instance space presents several unique challenges. These include but are not restricted to: (1) the need to maximize the coverage over the entire instance space of the compiler range, and (2) the ability to validate design performance and parametric yield sufficiently over the PVT range. It is essential therefore that SRAM verification is based on a variation-aware strategy.

These challenges also have to be addressed within a viable design timescale. To meet this goal, the overall verification task is split into several unique sub-tasks. These include:

- Behavioral model validation
- Full operating mode functional verification
- Top level variation aware parametric functionality
- Cell level parametric yield validation to $6\sigma$

Each of these tasks involves different levels of design abstraction and employs different simulation strategies and toolsets.

These challenges are made particularly onerous when verifying near-threshold SRAM solutions, such as the sureCore EverOn family. In order to realize significant power savings at the system level, this SRAM family operates across a very wide operating voltage range, from nominal supply voltage down to near-threshold operation. For example, in a commercially available 40ULP process node, the EverOn SRAM supports supply voltages from 1.21V down to 0.6V across process corners and temperature (from -40°C to 125°C). The memory is built around the foundry’s high-density low-leakage bitcell. Simulations have demonstrated that a combination of assist features achieves better than 6σ parametric cell yield in the worst PVT corner.

Near-threshold designs that provide such operating ranges demand an extensive approach to verification that relies on a range of validation strategies. These include focused parametric tests run with Monte Carlo (MC) analysis across the PVT range and high sigma analysis, using Solido Variation Designer software from Siemens EDA.

Within the context of SRAM development, the verification process is complimented by the characterization process that extracts data for a particular memory to facilitate SoC integration flows.
SureCore develops memory compilers that push the boundaries of low power performance. Obtaining high yield is essential, and achieving this while pushing such boundaries can only be achieved if variation considerations are the first step in the design, not an afterthought. Figure 1 shows a simplified depiction of sureCore’s design and verification approach.

One of the first steps in the design process is the high-sigma analysis of the cell operation and of the critical bit slice. For this, either the Solido High-Sigma Monte Carlo (HSMC) or Solido Hierarchical Monte Carlo (HMC) tool is used. This involves dedicated test benches to test cell read stability, writeability and read correctness (including cell, bit line and sense amplifier), as well as the offset of the sense amplifiers separately. In designs with hierarchical bit lines, additional test benches are required that include the global sense amplifiers and local write amplifier. For cell-level analysis, HSMC is the right tool, while HMC allows statistical correctness when considering slices where some instances occur more often than others, such as cells and sense amplifiers. In this first phase, ideal excitations are used for the control signals. Later in the design process, these simulations are repeated with the control signals as generated by the actual timing circuit. Although the tools provide a classifier approach that allows the use of non-smooth metrics such as binary outcomes, it is preferential to use well established metrics such as dynamic SNM$_{\text{read}}$ and WTP at this stage for the additional insights they provide. As these metrics are smooth and well understood, extrapolation of the distributions from a normal MC run to the tails might seem attractive – this however does not give sufficiently accurate estimates of the actual tail probabilities. When other metrics are used, such as the read current or vdd$_{\text{min}}$, extrapolation will lead to results that can be drastically inaccurate. As such an HSMC approach is mandatory.

Memory compiler verification is a considerable undertaking, so the memory design should aim at making verification as easy as is feasible given the other constraints – verification-aware design. This includes avoiding breakpoints in the instance space and limiting access pattern dependencies. Another crucial aspect is the development of effective slicing and reduction options, which provide crucial simulation speed-up. Together, they bring simulation time for a large memory instance down from 2 hours to 2.5 minutes and drastically reduce server memory load. These algorithms are implemented in the back-end compiler. By co-developing the memory design and the compiler, these simulation runtime improvements are not only available for verification and characterization tasks, but also to the design team.

When to use EverOn

Having a memory that can operate at any voltage between 0.6V and 1.21V greatly simplifies the design of systems that use aggressive voltage scaling to balance operating frequency and power dissipation. Logic and memory can use the same power supply, with their performance and power scaling together. There is no need for separate logic and memory power domains, level shifters at domain boundaries, and synthesis or P&R flows to handle multiple supplies. Design effort can focus on using voltage scaling to reduce application power rather than on trying to ensure it is implemented correctly.

Additional information can be found in sureCore’s white paper, “Addressing memory compiler characterisation challenges.”

Additional information on slicing and reduction can be found in sureCore’s white paper, “Efficient memory compilation.”

Verification

Behavioral validation
The sureCore memory compiler produces several views for system-level validation and integration. Amongst these is a behavioral back-annotatable Verilog model for RTL and gate level simulation. It is imperative that this model accurately reflects the behavior of the physical design. The sureCore memory compiler comprises of two parts: (1) the Front-End compiler (FEC) that creates views for the front-end of the design cycle (such as the behavioral Verilog model), and (2) the Back-End compiler (BEC) that creates all of the physical design views for final integration (GDSII/CDL). Functional accuracy of the Verilog model is validated using the FEC to generate the Verilog model and the BEC to generate an equivalent SPICE netlist. Both views are tested against a set of common tests and expected responses derived from the test stimuli, as shown in figure 2. The suite of test sequences is designed to cover the full range of operating configurations.

Variation-aware full-memory parametric verification
The sureCore verification flow includes a range of targeted parametric tests. In addition to validating basic functional write-read operations, these tests also validate parametric performance over the full range of specified PVT corner points. In the case of the sureCore EverOn family implemented on a 40ULP process node, these corners cover an operating voltage range from 0.6V to 1.21V and a temperature range from -40˚C to 125˚C. This is in addition to all the process corners.

The tests are run using Monte Carlo simulations that are executed at the top level, full memory instance view using sliced and reduced netlists. The netlist slice and reduction algorithms are separately validated for accuracy. The verification checks are structured to maximize test coverage across the compiler instance space.

Figure 2: Verilog versus SPICE verification flow.

SRAM functional specification
The functionality of an EverOn memory is a superset of that of an ordinary SRAM. In addition to addressing data_in, data_out, enable and read/notWrite ports, it also has multiple power-down modes and a control interface that allows timing and assist levels to be modified to compensate for reduced supply voltage. Input scan chains, data_in to data_out bypass, and BIST muxes are provided to enable integration into standard SoC test flows. To help with SoC integration the Verilog behavioral model includes checks that the power-down modes, and the timing and assist controls, are used correctly.

Variants of the basic EverOn memory are available that include one or more of:
- Per byte write enables
- Spare rows for yield improvement
Figure 3 shows a simplified depiction of the scripted parametric verification flow. It works by analyzing the saved waveform databases containing all signals at the full memory level from every Monte Carlo run performed on every selected PVT and instance space corner. Analyzing such complete waveform databases and comparing behavior across the different MC and corner runs allows a wealth of information to be extracted regarding the parametric health of the design, leading to the establishment of confidence in projected performance and yield capabilities. The parametric checks analyzed on every internal node include measurements on the signal transition times, pulse widths, signal levels and signal behavior consistency. The capabilities of the automatic checks are further enhanced by sureCore’s in-house Reconvergent Path Analysis tool, described in the next section. This tool determines all gates in the design with multiple active inputs and checks the relative order of these events. In addition to these generic checks, a set of targeted product family specific parametric tests are included in the standard flow. These product-specific
tests will differ between the sureCore EverOn and PowerMiser families and will include checks on identified critical parametrics such as the measured internal bit line voltages at the associated sampling trigger point (figure 4).

Information about each measured parametric test from every Monte Carlo batch run on each PVT/instance corner is collated into a summary report for ease of interpretation. The summary collates information about the maximum and minimum bounds observed on each parameter and measured against a specified test limit.

Figure 4: Example parametric distribution, one of many captured by the automatic parametric health checks. Even in the worst PVT corner (0.6V, SSG, -40°C), sufficient global bit line signal is available.
Reconvergent Path Analysis

To further strengthen the verification effort, sureCore developed a Reconvergent Path Analysis tool. This tool extracts all gates and their connectivity from the dspf netlist. A very limited amount of configuration has to be provided to properly deal with virtual supplies, pass gate logic and special constructs such as the local bit lines. This information is then combined with the simulation waveform database. One way to use this is to visualize the activity in the memory, as shown in figure 5. The triangles indicate rising and falling edges at the output of a gate; the lines between triangles indicate that one output signal is the input for another gate. Some special events are also highlighted. This interactive graph provides a wealth of information to the memory designer.

The same gate information can be used to extend the automatic verification flow. For gates that have multiple active inputs, the input events should always arrive in the same order for all MC runs. For example, for a WL driver, the output of the predecoders should be ready before the timed activation signal arrives, otherwise timing control is lost. When this happens in the tail of the distribution, de-coder delay variation causes word line pulse shrinking, which creates an unexpected heavy tail towards short word line pulse widths. If no explicit check on the order of these signal is in place, then it would be very easy to overlook this problem when running only a few thousand MC simulations since the issue doesn’t immediately manifest in the WL pulse width, let alone in the behavior at the IO ports. Reconvergent Path Analysis finds all gates with multiple active inputs and checks the distribution of the relative timing between the signals. If input order violations are likely to happen within the yield target, Reconvergent Path Analysis can flag these, even if the actual situation did not occur in the performed MC simulations.

Figure 5: Visualization of the activity inside the memory (read at reduced voltage with several assists enabled). The same information is used in Reconvergent Path Analysis.
Variation-aware yield analysis validation

As chips become more complex, the chance of failure also increases, making it difficult to measure the effects of variation on designs quickly and accurately. Often, extra margin is added to compensate for this uncertainty, sacrificing power, performance and area. Two available tools for SRAM yield analysis verification and validation from the Solido design automation portfolio include High Sigma Monte Carlo (HSMC) and Hierarchical Monte Carlo (HMC). Both of these variation-aware techniques meet requirements for fast, accurate, scalable, and verifiable techniques for reducing margins in near-threshold designs. These tools are an intrinsic part of the sureCore verification process.

The HSMC approach\(^1\) in Solido produces an accurate high-sigma (greater than 3\(\sigma\)) analysis of a distribution by optimizing the specific statistical sampling, reducing the number of required SPICE simulations to accurately realize a particular yield assessment. The HSMC approach prioritizes the cases that are most likely to fail, focusing on the worst-case scenarios, therefore streamlining the number of SPICE simulations required. This technique targets analysis on the extreme tail of a distribution, providing a lean process using fewer resources and simulations to analyze cases where verifiable analysis is most needed. Instead of running all simulations, HSMC provides accurate information in orders of magnitude fewer simulations, reducing over- or under-design in near-threshold situations.

HSMC can provide accurate information about the behavior of a design at the extreme tail of a distribution, making it an ideal tool for fast and accurate high-sigma Monte Carlo analysis. In bitcell analysis for example, HSMC is typically able to find the first 100 failures within the first 5,000 simulated samples. In traditional Monte Carlo analysis, finding the same number of failures would typically require up to 1.5 million samples, often without finding a single failure in the first 5,000 samples\(^4\). Including HSMC accurately accelerates the design loop by reducing potential design iterations and the need for over-margining in worst-case situations, which is of crucial importance for near-threshold designs. Similar behavior is observed in sense amp power consumption but all 100 failures can typically be found within the first 1,000 Monte Carlo samples.

As an extension of HSMC, Solido Hierarchical Monte Carlo (HMC) provides variation-aware statistical verification on critical paths, providing a lean process for fast, scalable, verifiable and accurate full memory Monte Carlo analysis. This is especially important when determining yield for the entire chip, including control logic, sense amps, and bit cells, where a simulation for a single instance can be time- and resource-intensive.

For example, in a case to achieve a desired overall yield of 3\(\sigma\) on a typical memory chip, required yield at the control logic-, sense amp-, and bitcell-level are 4.25\(\sigma\), 5.1\(\sigma\), and 5.95\(\sigma\), resulting in up to billions of Monte Carlo simulations to achieve full coverage (table 1). Current techniques to ensure full design coverage include potentially running all components to 6\(\sigma\), running local variation at FF and SS corners, and combining required yield from each sub-block assuming that all worst-cases occur simultaneously. Each of these strategies results in over-design and is very complex to implement.

<table>
<thead>
<tr>
<th>Component</th>
<th># of Replications</th>
<th># of Monte Carlo Simulations</th>
<th>Required Yield ((\sigma))</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control logic</td>
<td>128 (per chip)</td>
<td>1.81 million</td>
<td>4.25 (\sigma)</td>
</tr>
<tr>
<td>Sense amp</td>
<td>64 x 128 8,000</td>
<td>80.7 million</td>
<td>5.1 (\sigma)</td>
</tr>
<tr>
<td>Bitcell</td>
<td>128 x 64 x 128 1 million</td>
<td>7.56 billion</td>
<td>5.95 (\sigma)</td>
</tr>
</tbody>
</table>

Table 1. To achieve desired yield of 99.865% (3\(\sigma\), or 1 failure per 741) on a typical memory chip, required yield of each individual element ranges from 4.25\(\sigma\) to 5.95\(\sigma\), requiring billions of Monte Carlo simulations for full chip coverage.

Solido HMC provides accurate statistical reconstruction of the entire on-chip memory structure by building a statistical hierarchical reconstruction. It applies a similar sampling approach as HSMC, but carries out multiple parallel high-sigma analyses across each memory component (control logic, sense amp, bitcell) to meet the desired chip yield. This fast, verifiable technique optimizes chip yield and reduces over-design while still maintaining full variation coverage with Monte Carlo accuracy.

\(^4\) Ibid.
Near-threshold SRAM verification

Near-threshold designs such as the sureCore EverOn family demand an especially rigorous approach to verification. When operating at 0.6V in a 40ULP node (near-threshold), the delay of a regular logic gate can increase by more than a factor of 10 due to mismatch. As the delay dependency on $\Delta V_T$ is exponential as weak devices enter sub-threshold, the distribution of delay is strongly non-Gaussian, so extrapolations should be treated with extreme caution. Even when considering two paths consisting of larger devices, or of a long chain of gates, delay difference between the paths can vary dramatically between for example SFG and FSG if the paths are not identically exposed to NMOS and PMOS transistors. Incorrect internal timing sequences can be catastrophic, especially under low voltage operation. Because of this increased sensitivity to variation, care must be taken to cover an extended PVT corner range during verification and internal glitch conditions must be adequately examined.

Near-threshold operation poses a challenge for bitcell operation as standard foundry bit cells will not operate at lower level supply voltages. Alternative cells are much larger and have higher leakage and are hence not an attractive option. This necessitates the use of assist circuitry to deliver bit cell functionality and performance at low voltage. This does increase the number of critical events that need to be monitored and validated during the verification process, along with a need to verify the acceptability of the assist levels across the process and temperature corners, and across the instance space. To ensure high yield, sureCore performs HSMC simulations on the cell and bitslice in the worst case PVT corners, using excitations corresponding to the worst instance size. Even in these worst conditions and process corner, sureCore’s EverOn memories achieve a HSMC cell failure rate below 1e-9 (6-sigma).

Silicon validation

The ultimate proof of SRAM functionality is, of course, the behavior seen in a real chip. The EverOn memories described in this document have been subjected to extensive silicon validation by sureCore and by SoC developers. This work has demonstrated correct behavior across the expected range of temperature (-40°C to 125°C), voltage (0.6V to 1.21V) and process (using deliberately skewed MPW wafers to test SS, SF, FS, FF, and TT corners). Not only are the memories seen to be functional across the expected range, but there is close agreement between simulated and measured operating frequency and between simulated and measured power dissipation. This gives us confidence not just in the design of the EverOn memory, but also in the verification strategy described in this document.
Summary

Verification is the most critically important part of SRAM compiler development. Delivering low power SRAM solutions further exacerbates the challenges as near-threshold operation compounds multiple issues and increases the effects of process variation. This paper has highlighted some of the methodologies and tools sureCore uses in order to meet the challenges in a robust, practical and timely manner. Of course, this must be complemented by a similarly extensive silicon evaluation program, including cross PVT testing as well as HTOL validation to demonstrate long-term reliability. By combining these two elements, sureCore has demonstrated robust world beating low power memory for power critical applications.
